Significance statement: Can
two species thrive on a single
energetic resource? While the
competitive exclusion
principle predicts that one in
the pair should go extinct, it
may occur that an organism
releases partly metabolised
molecules in the environment,
securing an ecological niche
for a second organism in a
specialisation process called
metabolic cross-feeding. Here
we investigate how evolution
may favor the waste of a
useful resource using a model
that considers how a cell
packed with proteins may be
less efficient, hence favoring a
shortening of metabolic
pathways in order to reduce
cell packing. Our model
indicates that such
specialisation only occurs
under restricted conditions.
Incidentally, this makes the
signatures of cross-feeding,
such as which metabolites are
preferentially involved, quite
predictable.

9 Abstract

10 Metabolic cross-feeding (MCF) is a widespread type of ecological interaction where organisms
11 share nutrients. In a common instance of MCF, an organism incompletely metabolises sugars and
12 releases metabolites that are used by another as a carbon source to produce energy. Why would
13 the former waste edible food, and why does this preferentially occur at specific locations in the
14 sugar metabolic pathway (acetate and glycerol are preferentially exchanged) have challenged evo-
15 lutionary theory for decades. Addressing these questions requires to model the cellular features in-
16 volved; to this end, we built an explicit model of metabolic reactions, including their enzyme-driven
17 catalysis and the cellular constraints acting on the proteome that may incur a cost to expressing
18 all enzymes along a pathway. After showing that cells should in principle prioritise upstream reac-
19 tions when metabolites are restrained inside the cell, we investigate how the diffusivity of these
20 metabolites may trigger the emergence of MCF in a population. We find that the occurrence of
21 MCF is rare and requires that an intermediate metabolite be extremely diffusive: indeed, up to
22 high membrane permeability coefficients, the expected evolutionary outcome is not a diversifica-
23 tion that resembles MCF but a single genotype that instead overexpresses downstream enzymes.
24 Only at very high levels of membrane permeability and under distinctive sets of parameters should
25 the population diversify and MCF evolve. These results help understand the origins of simple mi-
26 crobial communities, and may later be extended to investigate how evolution has progressively
27 built up today's extremely diverse communities.

29 Introduction

30 Genetic diversification [1, 2] may occur when different ecological niches are encountered [3–5], for
31 instance when different carbon sources are available in the environment [6, 7]. What may at first
32 glance sound puzzling – why not using all the available nutrients? – finds an explanation in physi-
33 ological and environmental constraints or even absolute incompatibilities that make specialists of
34 each resource outperform generalists [8–13]. Even more bewildering is the observation that diver-
35 sification occurs in the homogeneous presence of a single energetic resource [14–17]. One finds a
36 clear example in chemostats or controlled experimental systems in which glucose is continuously
37 injected, where glucose consumers may evolve that release metabolites for others to use as carbon
38 sources [14, 18, 19]. This unidirectional by-product process is a form of metabolite cross-feeding
39 [20, 21], and its evolutionary underpinnings are still blurry [20, 22].

40 In particular, the reasons why specific metabolites are more likely involved in cross-feeding
41 remain unclear. Indeed, a large number of metabolites produced by a glucose-reliant organism
42 may constitute viable single carbon sources for others [for example, a glucose-reliant strain of *Es-*

43 *cherichia coli* can theoretically produce up to 58 useful metabolites, 22]. Yet only two metabolites
44 are commonly reported – from experiments – as being traded in such cross-feeding interactions,
45 namely acetate and glycerol [14, 19, 23, 24]. In line with the fact that some of these lineages may
46 have been predisposed to use these metabolites [23], San-Roman and Wagner [25] have hypothe-
47 sized that this preferential evolution could be due to shorter mutational paths. Accordingly, mod-
48 ifying the metabolic network to produce these interacting strains would require fewer and less
49 destabilising mutations and could thence arise more readily. But their conclusion is that acetate
50 or glycerol trades are no more likely than others to appear through mutation, making the mystery
51 about their involvement – and potential predispositions of strains – in the evolution of metabolic
52 cross-feeding even deeper.

53
54 Adaptation is often incomprehensible without considering the ability of an organism to per-
55 form a task as being dependent on internal constraints [26–29]. For example, fully expressing
56 all enzymes along a metabolic pathway may incur a fitness cost [30, 31], to such an extent that
57 sacrificing a part of a pathway becomes beneficial [32, 33]. Cells whose cytoplasm gets crowded
58 with proteins actually pay a two-fold cost [34]. First, producing enzymes incurs a direct energetic
59 expense, approximately proportional to the sum of enzyme concentrations in the cell [35–37]. Sec-
60 ond, cell packing eventually compromises the diffusion of proteins, thereby hindering metabolic
61 efficiency [38, 39].

62 In a previous study, we have shown that the evolution of enzyme kinetic parameters and con-
63 centrations is contingent on their competition with other processes for their substrate [34]. One of
64 these competing processes may be leakage through the cell membrane, such that highly diffusive
65 metabolites should be processed by more efficient or concentrated enzymes. The combination
66 of this requirement for high concentrations, and the cost of an abundant proteome, could make
67 these metabolites the preferential breakpoints in a metabolic pathway. Very few metabolites can
68 diffuse through membranes, either because of their size or due to their electronic properties [40].
69 Such diffusion may be direct, as is the case for glycerol, or indirect when a non-diffusive metabolite
70 can spontaneously transform into a diffusive one, as is the case with acetate [41, 42].

71
72 In this work – see Figure 1 for an overview of the metabolic model – we first determine how cells
73 should allocate their proteome when metabolite diffusion is limited. We find that upstream reac-
74 tions should be favored when selective pressures are similar along the pathway. We then assess
75 the hypothesis that cross-feeding evolves in response to the high diffusion rate of an intermediate
76 metabolite, due to the incurred selection on downstream enzymes. Indeed, a genotype produc-
77 ing the diffusive metabolite must also be very efficient at metabolising it to prevent its loss, and
78 thus pays a high cost over-expressing downstream enzymes that, at some point, may become in-
79 surmountable. Interestingly, a second genotype feeding on the intermediate metabolite and only
80 expressing downstream enzymes would thrive in this context where the metabolite has become
81 a resource. This is because, on top of saving on the expression of upstream enzymes, extensive
82 over-expression downstream is no longer a requirement as the high permeability coefficient of
83 the metabolite actually helps its uptake. Yet, the overall evolutionary process must be continuous,
84 instead of the schematic two-steps sequence presented here, making it difficult to predict when
85 the evolution of cross-feeding should occur.

86 In order to embrace this continuity, we use Adaptive Dynamics [43, 44] to model the evolu-
87 tion of the pattern of enzyme expression along the pathway. This framework is particularly suited
88 to model the complex ecological interactions that may arise as the genotype(s) composing the
89 population shape their environment [32, 45], by controlling the equilibrium frequencies of both
90 the nutrient and the diffusing metabolite. We find that MCF sometimes evolves, characterised by
91 an evolutionary diversification giving rise to the coexistence between a genotype only expressing
92 the enzymes upstream the diffusing metabolite, and another one expressing the enzymes down-
93 stream. This occurs at very high membrane permeability levels of the diffusing metabolite, only

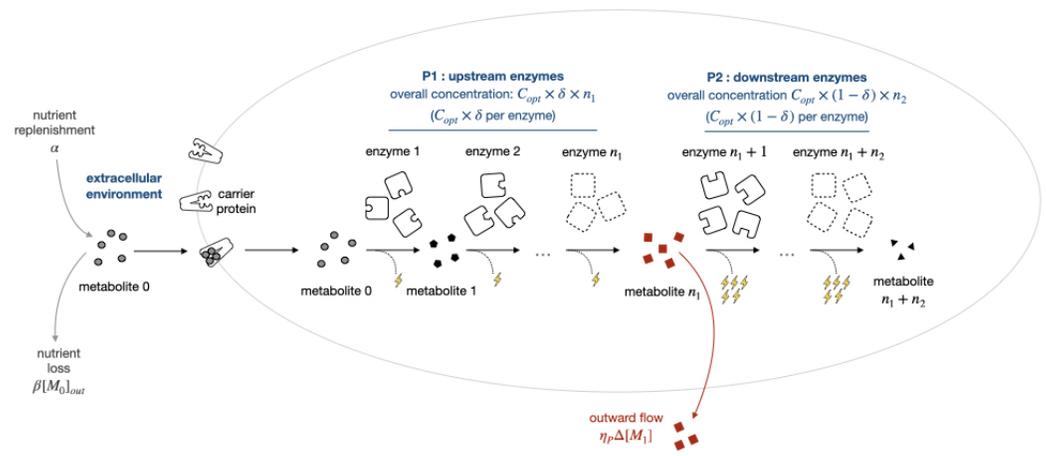

Figure 1. Overview of the model: the pathway is initiated by a carrier protein and comprised of n_1 upstream enzymes defining the sub-pathway P_1 and n_2 downstream enzymes defining the sub-pathway P_2 . Allocation of the proteome is driven by two parameters: (i) C_{opt} coincides with the adaptive proteome fraction dedicated to one of the reaction of the full pathway $P_1 + P_2$ when all enzyme concentrations are identical (the case of no differential allocation – see section Optimal metabolic allocation); (ii) the parameter δ (resp. $1 - \delta$) corresponds to the fraction dedicated to the first sub-pathway P_1 (resp. P_2). The extracellular dynamic of the nutrient (metabolite 0) is based on a constant replenishment-degradation process – see Materials and Methods section. Within the pathway, each reaction follows Briggs Haldane kinetics (with or without reversibility) where enzyme efficiency is constant and studied as a parameter. These reactions each provide a fitness yield, shown above as lightning, proportional to the amount of product produced and to the specific yield of energy gain set for reactions (1 energy unit per reaction per nutrient for upstream enzymes and 5 for downstream enzymes in the above example) – see section on overexpression. Fitness is simultaneously impeded by the cost of expression – production and crowding – and, depending on the subsection again, by the toxicity resulting from the total concentration of metabolites. The metabolite produced at the end of the upstream pathway P_1 is susceptible to leak through the membrane according to a permeability η_p – studied as a parameter – and the gradient of concentration between the extra and intracellular environments. Once in the extracellular environment, it is available to other cells but may also be degraded (like metabolite 0)

94 compatible with diffusion rates reported for acetate or glycerol. We also find that MCF requires
 95 moderate to high levels regarding the intracellular selective constraints acting on metabolites along
 96 the pathway.

97 Results

98 Optimal metabolic allocation and cell constraints

99 Evolution of the overall expression of metabolic enzymes

100 We first assume that all enzymes have an equal concentration and consider its evolution. Increas-
 101 ing concentration enhances the efficiency of catalysis and thus the production of energy, but with
 102 diminishing returns [34, 46]. It also incurs costs, firstly due to the actual energy cost of making
 103 proteins, and secondly because high protein concentrations in the cell decrease the efficiency of
 104 reactions due to cell packing. The former is captured in our model by a linear cost inflicted to extra
 105 production, and the latter through a penalty on k_f , whose effect has been estimated [39, 47] and
 106 modelled in previous studies [38] – [see Model and 34].

107 To approach the case of reactions involved in the carbon cycle [48], we consider a pathway
 108 comprised of 40 reactions and initiated by facilitated diffusion through a transporter [49], where
 109 energy is produced at each step in the process – see Figure 1 – and assessed the effect of reaction
 110 yield – see SM Figure S3. Reactions follow irreversible Briggs-Haldane kinetics [50], with kinetic
 111 constants set by default half an order of magnitude higher than the median observed for enzymes
 112 involved in the central metabolism [51] ($k_f = 10^{6.25} M^{-1} s^{-1}$, $k_{cat} = 10^{2.25} s^{-1}$) – see SM Table S2 for the

113 full set of parameters we used; besides, we also consider the case where reactions are reversible
114 – see SM Text S1.2. Setting these efficiencies above the average found for enzymes involved in
115 central carbon metabolism is conservative as it diminishes the selective pressure that promotes
116 higher enzyme expression, and thus ensures that we are not examining an implausible range of
117 values (*eg.* because the whole set would be biased by some enzymes that need not be efficient
118 due to specific metabolic features). The local context of reactions – including reaction reversibility
119 and metabolite toxicity – may also affect metabolic efficiency, as captured by a linear degradation
120 rate of each metabolite η in this instance of the model [34] – see SM Text S1.2 for more complex
121 selective pressures. Nutrients are added to the environment at a constant rate α and degraded at
122 a linear rate β – the latter also applying to metabolites released by cells in the medium (see below)
123 – whose levels are such that without cells, substrate concentration equilibrates at $1M$.

124 For all combinations of the parameters above considered, the evolutionarily expected concen-
125 trations of the 40 enzymes in the pathway sum up to 15 – 20 % of the whole proteome (see SM
126 – section Text S1). As we have shown previously, adaptive outcomes depend on a complex inter-
127 action between cell constraints, enzymes concentrations and kinetic efficiencies that cannot be
128 captured through the influence of classical experimenters' parameters (such as K_M or the activity
129 constant $k_{cat}[E_{tot}]/K_M$, for instance) alone [34]. The highest fraction is self-evidently obtained in
130 conditions where selection for the rates of reactions is acute, such that increasing concentration
131 becomes beneficial, to a certain extent, despite amplifying intracellular crowding and production
132 costs. These predictions are consistent with estimates among unicellular species [48]: in most
133 cases, enzymes involved in the carbon cycle constitute approximately 20 % of the proteome. In
134 the remaining of this study, the overall concentration of enzymes in the pathway is considered
135 fixed at its evolutionary expectation by default, *i.e.* that obtained for the specific combination of
136 parameters studied when assuming an identical allocation all along the pathway.

137 **Overexpression in upstream reactions**

138 We then studied how cells should distribute enzyme expression along a pathway split into two
139 parts of equal lengths. This is a proteome allocation problem, since the overall concentration is
140 fixed to an (adaptive) optimum as just described; we study the evolution of the part of this over-
141 all concentration allocated to the first half P_1 of the metabolic pathway, δ , which we assume can
142 change by mutation in the range $[0, 1]$ – $\delta = 0$ coinciding with no investment in P_1 such that all of
143 the resources are allocated to P_2 , while $\delta = 1$ corresponds to all resources being allocated to P_1
144 (and none to P_2).

145 The evolution of δ is modelled using adaptive dynamics [32, 43, 44], as is appropriate when the
146 fate of a mutant can depend on the environment shaped by one (or several) resident genotype(s).
147 Here the resident strategy may impact the equilibrium concentrations of the nutrient and of the
148 metabolites produced along the pathway. Nonetheless at this stage, each metabolite is considered
149 to be unable to diffuse across the membrane, such that their concentration in the environment re-
150 mains zero. Therefore in this case, the evolutionary outcome is always a single allocation strategy
151 δ , as exemplified in Fig. 2. In this figure, whatever the initial resident strategy in place in the pop-
152 ulation, evolutionary trajectories will converge to $\delta \approx 0.6$, and, once in place in the population (as
153 resident) this latter strategy will be stable against the invasion by mutants with any other δ . These
154 features make an enhanced expression of upstream reactions – with $\delta \approx 0.6$ – the evolutionarily
155 expected outcome, also described as a convergent stable strategy – CSS, hereafter.

156 In the presence of degradation, the adaptive investment in the first part of the pathway is gen-
157 erally above 0.5 : remarkably, δ evolves to more than 0.6 even at very low degradation rates where
158 the resulting loss in metabolites is less than 1% along the pathway (see Table S3 of SM for an
159 analysis of the influence of degradation on the loss of metabolites and Figure S5 of SM for more
160 details). One factor that pushes upstream expression towards higher adaptive values is the selec-
161 tive pressure imposed by transporters – see Figure S5-B of SM for the influence of transporters.
162 Yet, the process also holds when this influence is set apart. A plausible explanation is that within

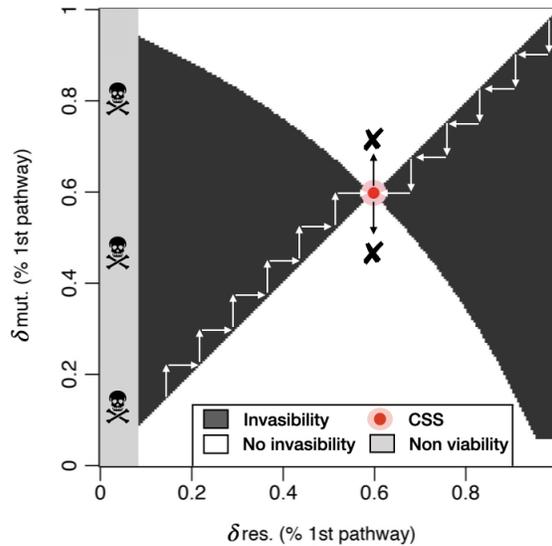

Figure 2. Example of the outcome of Adaptive Dynamics shown through a pairwise invasibility plot – PIP, hereafter – where black (resp. white) areas stand for positive (resp. negative) invasive fitness. The grey area represents an area where no strategy is viable because it cannot produce enough energy to reach the level set as corresponding to the demographic steady-state even when only one individual is present. When a mutant arrives in the population of resident strategies, it takes the place of the resident strategy if its invasion fitness is positive, a process represented by the white arrows. Here, below the CSS, mutants with higher values (black area above the left lower corner to right upper corner bisector) than the resident invades and evolution pushes resident to converge towards the CSS, while above the CSS, it is the other way around. This PIP shows how cells should spread their content, according to the respective fractions δ and $1 - \delta$, between upstream and downstream enzymes and exemplifies that under the specific set of parameters chosen, they should prioritise upstream reactions since $\delta > 0.5$, as was generally found – see text for more details.

163 an irreversible pathway as the one modelled, upstream enzymes not only concur to fitness directly through the energy generated by their respective reaction, but also through their indirect contributions to downstream reactions – see SM Text S2 and Figure S6 for the analysis of this phenomenon through a more tractable model showing that the optimal strategy should always be to prioritise upstream reactions. This is also consistent with the fact that this unequal allocation holds when downstream reactions produce far more energy than their upstream counterparts so that upstream reactions contribute mostly indirectly to fitness (and is significantly heightened in the opposite case): even when increasing the yield of the reactions in the second half of the pathway tenfold as described for the carbon cycle [52], δ remains close to 0.6. Besides, the irreversible loss of metabolites caused by an increase in the degradation rate increases the asymmetry in fitness contributions further and thereby tends to increase the adaptive ratio of upstream to downstream enzyme expression – see Figures S5 and S15 of SM.

175 Such asymmetries in fitness contributions might help explain why enzymes catalysing reactions more upstream tend to face stronger selection [53–55]. Overexpression of upstream enzymes can nonetheless be – at least, partly – counteracted by selection for homogeneity in metabolite concentrations, as is the case when toxicity is high (Figure S7-B of SM) and equally spread, and it also depends on reactions reversibility, including that of the transporter, inasmuch as reversibility also shifts the balance between direct and indirect contributions of each subpathway: if downstream reactions are more reversible than upstream ones, cells should prioritise them, and vice versa – see Figure S7-A of SM. Be that as it may, considering realistic combinations of these pressures – moderate toxicity and degradation rates as well as the average reversibility found in central carbon metabolism [56] tends to corroborate the need for upstream overexpression, as shown in Section

185 Text S2.2 of SM. One constraint that can reshuffle the deck of cards is the permeability of the cell
186 membrane, which was hitherto not considered.

187 **Membrane permeability and cross-feeding**

188 **Membrane permeability impacts proteome allocation**

189 Membranes are only permeable to a few metabolites, owing to their unique chemical features
190 [40]. In our model, we allowed the metabolite produced by the last reaction of the first half of
191 the metabolic pathway to diffuse – see the model overview in Figure 1 and the Model section for
192 details – with permeability rates ranging from $P = 10^{-12} \text{ dm}\cdot\text{s}^{-1}$ to $10^{-4} \text{ dm}\cdot\text{s}^{-1}$, in line with empirical
193 estimates [40]. Metabolites making their way across the membrane have two consequences. First,
194 they are lost for the cell that has produced them, which may act as a selective pressure for limiting
195 diffusion. Second, they may accumulate in the external environment and be available to other
196 individuals as a resource.

197 A cell has little leverage to limit outward diffusion; the most obvious solution is to use the
198 metabolite before it is lost, which in our model is possible through an increase in the concentration
199 of enzymes acting on the second part of the pathway. This is indeed what happens: the optimal
200 allocation shifts from a higher concentration in the first part of the pathway – owing to the afore-
201 mentioned factors – to a higher concentration in the second part as permeability increases, as
202 shown for instance in Fig. 3 in the case of a low degradation rate (grey dots). The results presented
203 in Fig. 3 are for proteins with kinetic parameters being slightly higher than the median reported for
204 enzymes in the carbohydrate and energy pathway [51]. Higher efficiencies consistently produce a
205 qualitatively similar result of a downward shift in allocation to the first part of the metabolic path-
206 way, P_1 , as permeability increases (see Figure S12 in SM). This outcome is also robust to the possible
207 existence of different energetic yields along a pathway – see Figure S8 for the influence of yield on
208 the optimal allocation – and most often holds when introducing other mechanistic constraints –
209 see Figures S13 and S14.

210 **High permeability coefficients can promote cross-feeding**

211 The overinvestment in the second part of pathway, P_2 , limits the loss of the leaky metabolite. As
212 permeability increases, the investment in P_2 must increase further, but this strategy becomes less
213 efficient such that the external concentration of the metabolite rises. This, in turn, may give a se-
214 lective advantage to genotypes that give up preventing the metabolite's leakage by increasing their
215 contribution to the first or second part of the pathway. From that point on, a new ecological niche
216 may emerge, that can ultimately result in an evolutionary diversification between two genotypes.
217 These situations can be identified by a specific type of pairwise invasibility plots where the singular
218 strategy is convergent but evolutionarily unstable – as shown in Fig. 3-C for the case of a high degra-
219 dation rate, the singular strategy at $\delta \approx 0.65$ can be invaded by nearby mutants – called a branching
220 point. An adaptive diversification may occur at a branching point, requiring that we study the fate
221 of mutants invading a pair of coexisting strategies, instead of a single one, through trait evolution
222 plots (SM Figure S9).

223 Branching points indeed lead to an adaptive diversification as the diffusion of the intermediate
224 metabolite increases above $10^{-6} \text{ dm}\cdot\text{s}^{-1}$, with the two most extreme strategies, $\delta = 0$ and $\delta = 1$,
225 evolving and forming a stable coalition (see SM - Text S3.1.2). This is characteristic of a complete
226 metabolic cross-feeding, where a genotype transforms a nutrient into a metabolite released in
227 the environment, and a second genotype feeds exclusively on that metabolite. For moderately
228 high permeability rates – around $P = 10^{-6} \text{ dm}\cdot\text{s}^{-1}$ – the evolutionary outcome is more dubious as
229 invasion is only possible by distant mutants; the result, in this case, will depend on the distribution
230 of mutational effects and cannot be studied using classic adaptive dynamics methods.

231 It should be noted that the results in Figure 3 correspond to a metabolic pathway with unequal
232 contributions of reactions to the energy needs of the cell (downstream reactions produce more

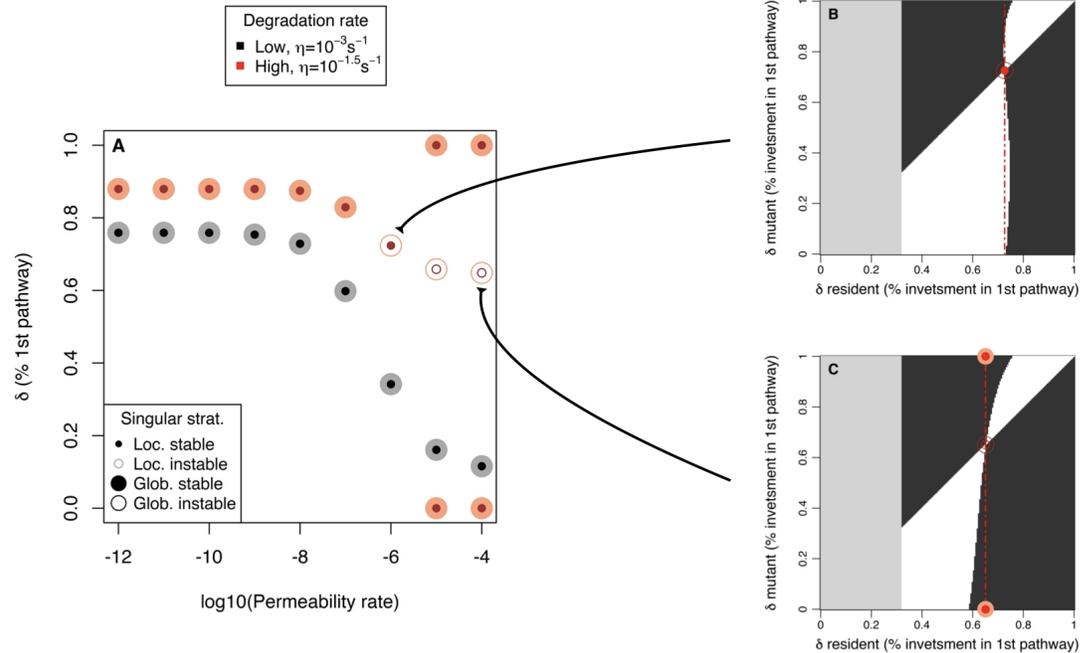

Figure 3. Permeability influences the evolution of strategies of enzyme allocations along a metabolic pathway, with the occurrence of cross-feeding at high permeability coefficients depending on the degradation rate. Two degradation rates are considered here (two other ones in Fig. S8 of SM) : low $\eta = 10^{-3} \text{ s}^{-1}$ in grey and moderate $\eta = 10^{-1.5} \text{ s}^{-1}$ in red. The enzymes catalysing reactions in either of two parts of the metabolic pathway, with their relative concentrations represented by δ (% 1st pathway), have kinetic parameters typical of those intervening in the carbon cycle ($k_f = 10^{6.25} \text{ M}^{-1} \cdot \text{s}^{-1}$ and $k_{\text{cat}} = 10^{2.25} \text{ s}^{-1}$); we also assume here that reactions in the second part P_2 of the pathway produce 10 times more energy than reactions in the first part P_1 . For low permeability rates (below $10^{-6} \text{ dm} \cdot \text{s}^{-1}$), the evolutionarily expected strategy is always globally and locally stable – as in Figure 2 – and consists in investing more in the first part of the pathway as discussed in the text – and described in further details through Fig. S5 and S15 (see the latter for the same enzyme efficiencies). Increasing permeability coefficients above $10^{-7} \text{ dm} \cdot \text{s}^{-1}$ results in a decrease in the investment in the first part of the pathway, δ , *i.e.* increasing the investment in the second part, remains the most efficient strategy. At low degradation rates (in grey on panel A), lowering δ , *i.e.* increasing the investment in the second part, remains the most efficient strategy. At high degradation rates (in red on panel A), however, high permeability coefficients result in singular strategies that are both convergent (they evolve from any starting δ) and evolutionarily unstable (they can be invaded by mutants with close (locally unstable) or distant (globally unstable) allocation strategy δ – see panel C). This can lead to adaptive diversification, resulting in a stable coalition of strategies, that is, a population made of coexisting genotypes with different values of δ . The coalition can be determined (see SM - Figure S9) ; it is comprised of genotypes with $\delta = 1$ (expressing only the first part of the pathway P_1) and of genotypes with $\delta = 0$ (expressing only the second part P_2), corresponding to metabolic cross-feeding. Panel B represents a permeability $P = 10^{-6} \text{ dm} \cdot \text{s}^{-1}$ for which the singular strategy is globally instable but locally stable, so that the evolutionary outcome should be contingent to the mutational landscape.

233 than upstream ones, as observed on average in the carbon cycle). Equalling the energy contribu-
 234 tions of all reactions often prevents the occurrence of cross-feeding. Yet, cross-feeding emergence
 235 was less sensitive to sub-pathway theoretical yields when we introduced the altogether realistic
 236 possibility of transporters and upstream enzymes co-expression, as exemplified on Figure S11.
 237 Reversibility and toxicity may also be involved in defining the critical point where cross-feeding
 238 coalitions can appear – see Section Text S3.3. Overall, the tipping point of $P = 10^{-6} \text{ dm} \cdot \text{s}^{-1}$ seems
 239 robust across all internal selective environments, albeit not being a sufficient condition as it also
 240 depends on the specific combination of constraints associated with these environments.

241 More generally, the evolution of cross-feeding appears contingent on many factors. For in-
 242 stance, selection on the overall concentration of enzymes contributing to the pathway is impor-

243 tant (eg. because it can reduce diffusive constraints), such that allowing higher concentrations
244 precludes the occurrence of cross feeding. This is because increasing downstream concentrations,
245 which may efficiently deal with metabolite diffusion, comes at a lower cost under these circum-
246 stances. This illustrates that the occurrence of cross-feeding may critically depend on the other
247 tasks – and their contributions to fitness, which was not directly considered here, though the degra-
248 dation rate may partly capture the behaviour – performed by cells and thereby on selection acting
249 on their dedicated proteome, as the global proteome concentration may only vary to a small ex-
250 tent [40]. No less important should be the size of cells since smaller ones mechanically come with
251 higher relative leakiness due to larger surface-to-volume ratios, which could in turn favor the occur-
252 rence of cross-feeding. Cells can nonetheless adapt their size to their content, at least to a certain
253 extent [37], which may limit the costs incurred by an increase in concentration and prevent the
254 occurrence of cross-feeding.

255 Finally, while in our model the efficiency of a reaction may only be changed through enzyme con-
256 centrations, kinetic parameters may also evolve and thus represent a relevant alternative in some
257 specific parts of the metabolic network. The evolution of cross-feeding could thus also be con-
258 tingent on the relative availability of mutations changing concentration *versus* kinetic parameters.
259 Therefore, while this model includes much of the available information about enzyme kinetics and
260 the selective constraints acting on the proteome, actually predicting how and when cross-feeding
261 should evolve will require more efforts to better understand the building of global epistasis along
262 metabolic networks and how critically this depends on the environment.

263 Discussion

264 The fact that few metabolites – acetate and glycerol, noticeably – are more likely involved in the
265 evolution of cross-feeding has been a conundrum for as long as experiments have revealed this
266 phenomenon [25]. Here, we have put forward an explanation based on the necessity for a cell to
267 optimise its proteome allocation, accounting for incurred costs and physical constraints like the dif-
268 ferential permeability of a cell's membrane to metabolites. Indeed, contrary to other metabolites,
269 acetate is in constant chemical equilibrium with the highly diffusive acetic acid [42], and glycerol
270 readily leaks towards the environment [40], which may predispose them to be involved in cross-
271 feeding.

272 That metabolites rather upstream in a metabolic pathway – and therefore of potential use to
273 generate more energy – will create a novel ecological niche when released is straightforward. But
274 whether evolution will take this path when some genotypes have the potential to reduce the leak
275 is worthy of a careful examination. In a number of cases that we have considered and that fall into
276 the realistic range of parameters, proteome allocation will evolve in such a way that it prevents, or
277 at least limits, the diffusion of the molecule. Only under some restricted conditions – that we have
278 shown to coincide with the features of the two aforementioned metabolites – will cross-feeding
279 evolve, characterised by a functional specialisation between a part of the population that trans-
280 forms the nutrient into the diffusive metabolite, and another part that uses the metabolite as a
281 carbon source, echoing work on digital evolution that similarly pointed to the possible contingency
282 of cross-feeding [57, 58].

283
284 Beyond the existence of intrinsic cellular leakiness, one process that may facilitate the emergence
285 of cross-feeding, or that may be co-opted to foster its efficacy when it is in place, is the cheap
286 uptake and secretion of metabolites (eg. through facilitated transport) [42, 59, 60]. Even a slight
287 leakage may for instance be enough to sustain a cross-feeder with high affinity transporters such
288 as the one reported in *E.coli* for acetate [61]. This metabolic strategy, where cells actively give up
289 a metabolite even though it still has the potential to bring fitness contributions, is often known
290 as overflow metabolism [62, 63] and also frequently involves acetate. We did not consider the
291 existence of a specific cost to the second part of the pathway, as has been documented in the past

292 to explain overflow [64, 65]; nor did we account for other possible costs such as the existence of
293 a localised toxicity [66] or the extra membrane occupancy involved in cellular respiration [67, 68].
294 These processes may promote the advent of cross-feeding, for they could bring extra fitness to an
295 organism expressing one or the other part of the pathway.

296 From a broader ecological perspective, nutrients are hardly ever constantly renewed in nature;
297 they are subject at least to some stochasticity, and most often than not occur through unpredictable
298 periods of feast and famine. Insight into how proteome allocation may evolve in this context, and
299 whether it should likely involve cross-feeding, can be gained from the existence of so-called diauxic
300 shifts, where the phenotype can switch from the production of acetate to its consumption when the
301 medium is enriched in this nutrient [59, 69]. In this case, it appears that the environment could be
302 used to store intermediate metabolites, both increasing a genotype's ability to uptake and use
303 glucose when it is present, and its ability to await its renewal otherwise. Such plasticity in
304 expressing different parts of a metabolic pathway should prevent, to some extent, the evolution of
305 fixed specialists (as considered here) and further hinder the evolution of cross-feeding. We thus
306 postulate that cross-feeding might only evolve in environments stable enough to prevent the evolution
307 of plasticity.

308 Biology is actually teeming with interactions and emergent properties that complicate the big
309 picture [70]. And, if functional simplicity may exist at the ecological scale [71], the ultimate under-
310 pinnings behind community assemblies are still blurred by the combination between a long and
311 tumultuous evolutionary history and the wide prevalence of high order interactions, both within and
312 between organisms, and in relation to the environment [57, 72, 73]. Addressing these community-
313 level questions cannot bypass the existence of lower level features such as the epistatic relationships
314 stemming from the joint effect of enzyme kinetic parameters [74] and their expression along
315 pathways [75]; nor can we study metabolic evolution without a careful examination of their impact
316 on the cellular micro-environment. We believe that the present study, by accounting for these
317 interactions at a primordial ecological stage, will help explain how (some of) these communities
318 appeared in the first place and how this may have then fuelled the scaffolding process underlying
319 the building of microbial societies.

320 Models

321 Metabolic Model of fitness

322 Cell fitness results from the biomass and energy produced along a metabolic pathway (eg. ATP).
323 The pathway is initiated by carrier proteins with $V_{T_m} = 1mM/s$ and $K_T = 10mM$ (see SM Text S1 for
324 details and justification), passively transporting nutrients inside cells and whose features are based
325 on those for glucose in yeasts, as detailed elsewhere [34]. Nutrients are added (resp. eliminated) at
326 a constant rate α (resp. β) in the external environment. The metabolic pathway is linear, comprising
327 N_r (40 in the paper, but see SM for other values) reactions catalysed by enzymes whose levels of
328 expression may evolve. The product of the j^{ieth} reaction is used as the substrate of the next one.
329 These metabolites are constantly degraded at a rate η or fuelling toxicity T according to processes
330 justified elsewhere [34] and also detailed at the beginning of the SM (introduction of section Text S1
331 and subsection Text S1.2). Each reaction (j) follows either reversible or irreversible Briggs Haldane
332 kinetics [76]:

Irreversible reactions are modeled by setting $k_{inh} = 0$ - in this simple setting, the system can be solved for each pair of successive reactions since they do not feedback on upstream reactions, so that one has to solve N quadratic equations of the form:

$$V m_j \frac{[S_j]}{[S_j] + K_{M,j}} = V m_{j+1} \frac{[S_{j+1}]}{[S_{j+1}] + K_{M,j+1}}, \quad (2)$$

333 where V_m and K_M depends on microscopic parameters k_f and k_{cat} , as well as enzyme concentra-
334 tions while η is the degradation rate (leakiness is modelled in a similar manner than the degrada-
335 tion rate but depends on the gradient between internal and external concentrations so that it also
336 impacts the environment through the latter). Otherwise, reversibility is spread equally between
337 backward parameters k_r and $k_{inh,act}$ (eg. if $K_{rev} = 1/9$, $k_r = k_{cat}/3$ and $k_{inh,act} = k_{f,act}/3$) and the system
338 of N equations is solved using Broyden's method [77]. The actual values for $k_{inh,act}$ and $k_{f,act}$ depend
339 on the cellular constraints – see next subsection of Model.

340 Each reaction produces energy. This is a simplification as some reactions in the carbon cycle do
341 not, unimportant as we consider the global expression of large portions of a pathway. We consider
342 the case where contributions are equal along the pathway as well as other more realistic setups.

343 Cellular constraints

344 Cell proteomes face two intrinsic constraints: (i) the cost of protein expression and (ii) the burden
345 entailed by molecular crowding. We model (i) through a cost linear with protein expression, pro-
346 portional to constant c [36]. We considered values of c such that the whole cytoplasmic proteome
347 – the enzymes in the pathway and other free enzymes – costs 5 to 50% of the whole cell budget. We
348 model molecular crowding (ii) through a non-linear decrease of diffusion [38, 39] that changes the
349 affinity constant k_f to $k_{f,act}$ in the model with irreversible reactions, according to equation:

$$k_{f,act} = k_f \cdot 10^{-([E_{other}] + \sum_{i=1}^{40} [E_{tot,i}]) / [M_b]}, \quad (3)$$

350 where $[E_{tot,i}] = [E_i] + [ES_i]$, $[M_b] = 3 \cdot 10^{-3} M$ represents the scaling factor for the effect of diffusion,
351 while $[E_{other}]$ denotes the sum of the concentrations of other cytoplasmic proteins than the 40
352 under consideration. In the model with reversible reactions, k_{inh} is also affected by crowding, which
353 is a conservative assumption as reverse reactions might be less sensitive to the diffusive process
354 owing to the preexisting co-localisation between substrate molecules and enzymes.

355 Our model includes three processes involving the metabolites produced that select for the en-
356 hancement of enzyme activity, drawing a complex trade-off on the coexpression of enzymes: (1)
357 metabolites can be lost, either because they are involved in parasitic reactions or because they are
358 subject to targeted degradation [78], modelled through a linear degradation rate η ; (2) metabolites
359 can be toxic for the cell, for they engage in parasitic reactions, for instance through promiscuous in-
360 teractions [79]; (3) highly reversible reactions within a pathway may also require efficient enzymes
361 to maintain a high net flux [80]. We considered these three processes in various instances of our
362 model, as described in SM Text S1; the results presented in the paper mainly comprise the action
363 of a linear degradation rate, which provides a good qualitative understanding of how processes
364 impacting the metabolites also impact selection on enzymes. Finally, the permeability of cell mem-
365 brane to a given metabolite also acts as a constraint, which is introduced here by considering that
366 one metabolite in the pathway diffuses passively at a rate η_d – on Figure 1, we show where this
367 process occurs.

368 Ecological equilibria

369 As to perform the adaptive dynamics analysis, we need to determine the ecological equilibrium set
370 by a given genotype or coalition. To this aim, we first compute the value of the net flux (number
371 of energy units per individual per unit of time) $\Phi_{net,N}$ for a given population size N . As long as this
372 flux is lower (or higher) than an arbitrary value $\Phi_{net} = 10^{-4} M \cdot s^{-1}$, N is increased (or decreased)
373 at the next iteration (by one unit when the flux gets close enough from this value). The algorithm
374 is stopped, either when the difference between these fluxes is lower than $10^{-6} \Phi_{net}$, or when it os-
375 cillates between two neighbouring values (N_{eq} is then set to the average between these values).
376 The ecological equilibrium, is defined by the nutrient and metabolite concentrations in the envi-
377 ronment at this demographic equilibrium. Fitness values of strategies are then calculated in these
378 conditions of equilibrium.

379 **Adaptive Dynamics of enzyme expression**

380 We use Adaptive Dynamics [32, 43, 44] to model the evolution of enzyme expression along the
381 metabolic pathway. This framework consider rare mutations, such that a resident “strategy” – cor-
382 responding to a given expression pattern – is assumed to have reached its demographic equilib-
383 rium before a mutant strategy appears in the population. At this demographic equilibrium, births
384 compensate for deaths in the population, resulting in a concentration of nutrients specific of the
385 resident (see previous section). The fitness of any mutant strategy is then determined for each
386 resident equilibrium, which enables the drawing of Pairwise Invasibility Plots (PIPs) representing
387 for each pair the ability of a rare mutant to invade the resident strategy, based on a comparison
388 between the growth rate of the mutant and that of the resident. These plots are used to identify
389 singular strategies and their properties, as defined in [43]. A particular type of singular strategies,
390 branching points, may be indicative of a diversification in the population, which we further study by
391 drawing areas of mutual invasibility (where both strategies invade when rare), before computing
392 the ecological equilibrium for each coalition – composed of two resident strategies instead of one
393 – in that space. We then calculate the growth rate of mutants nearby each strategy in the coalition
394 to identify coalitions that are stable (they cannot be invaded by any of the nearby mutants) and
395 convergent (there exist evolutionary trajectories towards them), hence identifying evolutionarily ex-
396 pected communities after diversification has occurred [81, 82]. This latter process is summarised
397 on trait evolution plots – TEPs – that we have shown in SM.

398 PIPs were generally drawn for 250 strategies, unless lower resolution was sufficient to capture
399 the trend. In order to determine the optimal allocation, we set the total proteome content to its
400 optimal value as determined without the influence of permeability. An individual whose strategy
401 is to invest as much in the first part of the pathway than in the second part corresponds precisely
402 to this case. Notice that, besides using a two step process, solving the systems to find nutrient and
403 metabolite concentrations required to use R package ‘nleqslv’ with Broyden’s method [77].

404 **Settings for the models**

405 A list of the basic settings can be found at the end of section Text S1.1 - SM. We varied them within
406 their biological realistic ranges. This allowed us to identify key drivers of the diversification process
407 that eventually result in cross-feeding, as discussed in the results section. The extensive analysis
408 of parameters can be found in SM, especially in Texts S1 and S3.

409 **Acknowledgment**

410 We thank T.Lenormand for helpful discussions that led us to consider the evolution of cross-feeding.
411 This preprint was created using the LaPreprint template (<https://github.com/roaldarbol/lapreprint>) by
412 Mikkel Roald-Arbøl.

413 **Author contributions**

414 FL, ER, FM and VD designed the research. FL and ER developed the models and analyzed the results.
415 FL and ER wrote the first draft while FM and VD contributed further improvements.
